Configuring TCP

HTTP is an application-based protocol, which uses TCP as the transport layer. In TCP, data is transferred in the form of packets. NGINX provides directives to alter the behavior of the underlying TCP stack. These parameters alter flags for an individual connection.

TCP_NODELAY

TCP/IP networks have the "small packet" problem, where single-character messages can cause network congestion. In TCP, packets are 41 bytes in size, where 40 bytes are for the TCP header and 1 byte has useful information. These small packets can cause a network to be around 4000 percent slower and can saturate a network.

John Nagle solved the problem (Nagle's algorithm) by not sending the small packets immediately. All such packets are buffered and then sent in one go as a single packet. This results in the improved efficiency of the underlying network. The delay can be up to 200 milliseconds before sending the data packages to the client.

It is important to note that the problem exists with applications such as Telnet, where each keystroke is sent over wire. If you are using a web server, which serves static files. The files will mostly form full TCP packets, which can be sent immediately instead of waiting for milliseconds.

The `TCP_NODELAY` option can be used while opening a socket to disable Nagle's buffering algorithm and send the data immediately. NGINX provides the `tcp_nodelay` directive to enable this option. The directive is available under the `http`, `server`, and `location` sections of an NGINX configuration:

```
http{
    tcp_nodelay on;
}
```

The directive is enabled by default.

Note

NGINX uses `tcp_nodelay` for connections with the keep-alive mode.

TCP_CORK

As an alternative to Nagle's algorithm, Linux provides the `TCP_CORK` option. The option tells the TCP stack to apply Nagle's algorithm when they are full or when the application instructs to send the packet by explicitly removing `TCP_CORK`. This results in fewer packets being sent and, thus, improves the efficiency of the network. The `TCP_CORK` option is available as the `TCP_CORK` option on Linux and Mac OS.

NGINX provides the `tcp_nopush` directive to enable `TCP_CORK` over the connection socket. The directive is available under the `http`, `server`, and `location` sections of an NGINX configuration:

```
http{
    tcp_nopush on;
}
```

The directive is disabled by default.

Appendix A: Index

NGINX uses `tcp_nopush` for requests served with `sendfile`.

Setting them up

The two directives discussed previously do mutually exclusive things; the former makes sure that the network latency tries to optimize the data packets sent. An application should set both of these options to get efficient data transfer.

Enabling `tcp_nopush` along with `sendfile` makes sure that while transferring a file, the kernel creates the packets before sending them over wire. The last packet(s) can be partial TCP packets, which could end up waiting with NGINX makes sure it removes `TCP_CORK` to send these packets. Since `tcp_nodelay` is also set at this point, the data is sent over the network without any delay.
